

DIGONS AND ANGULAR DERIVATIVES OF ANALYTIC SELF-MAPS OF THE UNIT DISK

MANUEL D. CONTRERAS, SANTIAGO DÍAZ-MADRIGAL,
AND ALEXANDER VASIL'EV

ABSTRACT. We present a geometric approach to a well-known sharp inequality, due to Cowen and Pommerenke, about angular derivatives of general univalent self-maps of the unit disk.

1. INTRODUCTION

Let $\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\}$ be the unit disk and $\text{Hol}(\mathbb{D}, \mathbb{D})$ be the family of those analytic maps defined on $\mathbb{D}$ and with values also in $\mathbb{D}$. Obviously, $\text{Hol}(\mathbb{D}, \mathbb{D})$ forms a semigroup with respect to the functional composition with the identity map as the neutral element. In this iteration context, the study of fixed points has always played a prominent role. We recall that a point $\xi \in \overline{\mathbb{D}}$ is said to be a fixed point of a function $\varphi \in \text{Hol}(\mathbb{D}, \mathbb{D})$ whether $\lim_{r \rightarrow 1} \varphi(r\xi) = \xi$. Besides, when $\xi \in \partial\mathbb{D}$, this is indeed equivalent to assert that the angular limit $\angle \lim_{z \rightarrow \xi} \varphi(z) = \xi$, that is to say, $\lim_{z \rightarrow \xi, z \in \Delta_\xi} \varphi(z) = \xi$ for any Stolz angle Δ_ξ centred on ξ . Those points $\xi \in \partial\mathbb{D}$ are usually called boundary fixed points of φ . It is a remarkable fact that we can always talk about the multiplier of this boundary fixed point ξ in the sense that the following angular limit exists

$$\varphi'(\xi) := \angle \lim_{z \rightarrow \xi} \frac{\varphi(z) - \xi}{z - \xi}.$$

In fact, $\varphi'(\xi) \in (0, +\infty) \cup \{\infty\}$ and when $\varphi'(\xi) \neq \infty$, we say that ξ is a regular (boundary) fixed point. Moreover, these regular fixed points can be attractive if $\varphi'(\xi) \in (0, 1)$, neutral if $\varphi'(\xi) = 1$ or repulsive if $\varphi'(\xi) \in (1, +\infty)$. Those fixed points $\xi \in \mathbb{D}$ with $|\varphi'(\xi)| < 1$ are also named attractive.

A classical result by Denjoy and Wolff states that for a holomorphic self-map φ of the unit disk $\mathbb{D}$ other than a (hyperbolic) rotation, there exists a unique fixed point $a \in \overline{\mathbb{D}}$ such that the sequence of iterates $(\varphi_n(z))$ converges locally uniformly on $\mathbb{D}$ to a as $n \rightarrow \infty$. This point a is called the Denjoy-Wolff point of φ and it is also

characterized as the only fixed point of φ satisfying $\varphi'(a) \in \mathbb{D}$. In other words, a is the only attractive fixed point of φ in the above multiplier sense. It follows from the hyperbolic metric principle that, if φ is not the identity, there can be no other fixed points in $\mathbb{D}$ except the Denjoy-Wolff point but, nevertheless, φ can have many other repulsive or non-regular boundary fixed points.

One of the most studied properties concerning fixed points has been and is to understand the relationship, if there is any, between the different fixed points and their multipliers of a general function $\varphi \in \text{Hol}(\mathbb{D}, \mathbb{D})$. At this respect, Cowen and Pommerenke proved the following nice result.

Theorem 1.1. [4] *Let $\varphi \in \text{Hol}(\mathbb{D}, \mathbb{D})$ be univalent with an attractive Denjoy-Wolff point $a \in \partial\mathbb{D}$, and let $\xi_1, \dots, \xi_n$ be n different repulsive boundary fixed points of φ . Then,*

$$\sum_{k=1}^n \frac{1}{\log \varphi'(\xi_k)} \leq -\frac{1}{\log \varphi'(a)}.$$

Moreover, this inequality is sharp.

As far as we know, there are two proofs of the above result in the literature. One of them is the original one due to Cowen and Pommerenke and relies on the so-called Grunsky-type inequalities. Later on, Li [5] obtained an alternative proof based on the theory of contractively contained spaces, sometimes also called de Branges-Rovnyak spaces. Undoubtedly, both approaches have a definite heavy analytic flavour. In this paper, we provide a strictly geometric proof of this inequality which, apart from its own interest, allows us to improve it in a certain sense. Moreover, this point of view also suggests to state it in a "weighted" way. Namely, we will prove the following.

Theorem 1.2. *Let $\varphi \in \text{Hol}(\mathbb{D}, \mathbb{D})$ be univalent with an attractive Denjoy-Wolff point $a \in \partial\mathbb{D}$, and let $\xi_1, \dots, \xi_n$ be n different repulsive boundary fixed points of φ . Likewise, consider n non-negative numbers $\alpha_1, \dots, \alpha_n$, such that $\sum_{k=1}^n \alpha_k = 1$. Then,*

$$\prod_{k=1}^n \varphi'(\xi_k)^{\alpha_k^2} \geq |\varphi'(a)|^{-1}.$$

Moreover, this inequality is sharp.

We want to mention that this theorem can also be considered as the 'boundary' version of a recent result due to Anderson and Vasil'ev [1]. At the same time, a question naturally appears when comparing the above Theorems 1.1 and 1.2 and it is to explain the exact relationship between them. To this aim, we need to use a simple fact from Calculus: consider the function

$$f : D \subset \mathbb{R}^n \rightarrow \mathbb{R} \quad \alpha \mapsto f(\alpha) = \sum_{k=1}^n \alpha_k^2 c_k,$$

where $D := \{\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbb{R}^n : \alpha_1, \dots, \alpha_n \geq 0 \text{ and } \sum_{k=1}^n \alpha_k = 1\}$ and $c_1, \dots, c_n$ is an arbitrary family of n non-negative numbers. Then, applying Lagrange multiplier Theorem, we have that f attains its minimum at the point $\alpha = \frac{1}{\sum_{k=1}^n c_k} (c_1, \dots, c_n) \in D$.

Now, doing some computations and setting

$$(\alpha_1, \dots, \alpha_n) := \frac{1}{\sum_{k=1}^n \log \varphi'(\xi_k)} (\log \varphi'(\xi_1), \dots, \log \varphi'(\xi_n))$$

in Theorem 1.2, we see that we can recover Theorem 1.1. At the same time, this argument also shows that, putting together all the weight inequalities, there is one which is the best and this one is the original inequality of Cowen and Pommerenke. Anyhow, it is worth recalling that all the weighted inequalities are sharp. Indeed, in sections three and four we present two different manners of obtaining those functions giving equality in such weighted inequalities. These two ways correspond to techniques from fractional iteration (section three) and from the theory of quadratic differentials (section four).

2. DIGONS, MODULI, AND PROOF

2.1. Digons and their reduced moduli. A digon in the complex plane is a triple (D, a, b) , where D is a hyperbolically simply connected domain with piecewise smooth boundary and a, b are two finite points belonging to ∂D called its vertices. As usual, the vertices a, b will be sometimes omitted when speaking about digons. The main number associated with a digon is its reduced modulus $m(D, a, b)$ which is defined by means of the concept of modulus of a simply connected domain with respect to a family of paths lying in the domain (see also [9, Sections 2.1 and 2.2]). Not always this reduced modulus exists but this will be the case in our context. For more general conditions which guarantee the existence of this reduced modulus, we refer the reader to [8] and [9, section 2.2.3].

Anyhow, more than working with single digons in the complex plane, we will be really interested in dealing with certain families of non-overlapping digons in the unit disk. Namely, consider an admissible system of curves on $\mathbb{D}$, that is, a finite number $\gamma := (\gamma_1, \dots, \gamma_n)$ of simple arcs not homotopically trivial on $\mathbb{D}$ that are not freely homotopic pairwise on $\mathbb{D}$, which start and finish at fixed points of $\partial \mathbb{D}$, are not homotopic to a point in $\mathbb{D}$ and do not intersect. In this context, a system of non-overlapping digons $(D_1, \dots, D_n)$ on $\mathbb{D}$ is said to be of homotopic type $(\gamma_1, \dots, \gamma_n)$ if $(\gamma_1, \dots, \gamma_n)$ is an admissible system of curves on $\mathbb{D}$ and for any $k \in \{1, \dots, n\}$, any arc on $\mathbb{D}$ connecting the two vertices of D_k is homotopic (not freely) to γ_k .

Likewise, we fix a height vector $\alpha = (\alpha_1, \dots, \alpha_n)$ and we will also require the digons to satisfy the so-called conditions of compatibility of angles and heights or just associated conditions with α , i.e.,

$$\delta_k(a_k) = \frac{\pi \alpha_k}{\sum_{j \in I_{a_k}} \alpha_j}, \quad \delta_k(b_k) = \frac{\pi \alpha_k}{\sum_{j \in I_{b_k}} \alpha_j}, \quad k = 1, \dots, n,$$

where I_c is the set of indices which refers to the digons D_j with a vertex at c . At the same time, $\delta_k(a_k) := \sup \Delta_{a_k}$ and $\delta_k(b_k) := \sup \Delta_{b_k}$ are the inner angles of the digon D_k , that is, Δ_{a_k} (resp. Δ_{b_k}) is the opening of a Stolz angle inscribed in D_k at a_k (resp. b_k).

2.2. Proof of Theorem 1.2. Let a be an attractive Denjoy-Wolff boundary point in $\partial\mathbb{D}$ as in Introduction. Consider an admissible curve system γ in $\mathbb{D}$ with $\gamma := (\gamma_1, \dots, \gamma_n)$, and where each γ_k is a simple arc starting at a and finishing at the repulsive fixed point ξ_k . According to [8], we can find an extremal system of non-overlapping digons $(\widehat{D}_1, \dots, \widehat{D}_n)$ of homotopy type γ and satisfying the compatibility conditions associated with the vector $\alpha := (\alpha_1, \dots, \alpha_n)$ given in Theorem 1.2. Since φ is univalent and $a, \xi_1, \dots, \xi_n$ are regular boundary fixed points of φ , we see that $(\varphi(\widehat{D}_1), \dots, \varphi(\widehat{D}_n))$ is again a system of non-overlapping digons of homotopy type γ and satisfying the compatibility conditions associated with α . In particular, the reduced modulus is well-defined for each $\widehat{D}_k$ and each $\varphi(\widehat{D}_k)$. Hence, by the extremal character of the first system [9, Section 2.7.1], we have that

$$\sum_{k=1}^n \alpha_k^2 m(\varphi(\widehat{D}_k), a, \xi_k) \geq \sum_{k=1}^n \alpha_k^2 m(\widehat{D}_k, a, \xi_k).$$

Now, applying the change-variable formula [9, Theorem 2.2.2], we deduce that

$$\begin{aligned} \sum_{k=1}^n \alpha_k^2 m(\widehat{D}_k, a, \xi_k) &\leq \sum_{k=1}^n \alpha_k^2 m(\widehat{D}_k, a, \xi_k) \\ &\quad + \sum_{k=1}^n \alpha_k^2 \left(\frac{1}{\delta_k(a)} \log \varphi'(a) + \frac{1}{\delta_k(\xi_k)} \log \varphi'(\xi_k) \right). \end{aligned}$$

Since

$$\delta_k(a) = \frac{\pi \alpha_k}{\sum_{j=1}^n \alpha_j} = \pi \alpha_k \text{ and } \delta_k(\xi_k) = \frac{\pi \alpha_k}{\alpha_k} = \pi,$$

we conclude that

$$0 \leq \pi \sum_{k=1}^n \alpha_k^2 \left(\frac{1}{\pi \alpha_k} \log \varphi'(a) + \frac{1}{\pi} \log \varphi'(\xi_k) \right) = \log \varphi'(a) + \sum_{k=1}^n \alpha_k^2 \log \varphi'(\xi_k).$$

The proof ends by taking exponentials in the above inequality.

3. ATTAINING THE EQUALITY BY MEANS OF FRACTIONAL ITERATION

Let us recall that a *(one-parameter) semigroup of analytic functions* is any continuous homomorphism $\Phi : t \mapsto \Phi(t) = \varphi_t$ from the additive semigroup of non-negative real numbers into the composition semigroup of all analytic functions which map $\mathbb{D}$ into $\mathbb{D}$. That is, Φ satisfies the following three conditions:

- a) φ_0 is the identity in $\mathbb{D}$,
- b) $\varphi_{t+s} = \varphi_t \circ \varphi_s$, for all $t, s \geq 0$,
- c) $\varphi_t(z)$ tends to z locally uniformly in $\mathbb{D}$ as $t \rightarrow 0$.

It is well-known that the functions φ_t are always univalent. If a is the Denjoy-Wolff point of one of the functions φ_{t_0} , for some $t_0 > 0$, then a is the Denjoy-Wolff point of all the functions of the semigroups, that is, all the functions of the semigroup share the Denjoy-Wolff point. Moreover, if a point $\xi \in \partial\mathbb{D}$ is a boundary fixed point of φ_{t_0} , for some $t_0 > 0$, then it is a boundary fixed point of all φ_t [3].

An important characteristic of a semigroup Φ is given by its Koenigs functions. We will recall this notion just when the Denjoy-Wolff point a is in the boundary of the unit disk. In this case, there exists a unique univalent function $h : \mathbb{D} \rightarrow \mathbb{C}$ such that $h(0) = 0$, and for every $t \geq 0$,

$$h \circ \varphi_t(z) = h(z) + t \quad (z \in \mathbb{D})$$

(see, for example, [7]). The function h is called the Koenigs functions of Φ . Let us write $\Omega = h(\mathbb{D})$, and let $\nu(\Omega)$ be the supremum of all positive numbers y such that there is $c \in \Omega$ with

$$\{c + it : -y/2 < t < y/2\} \subset \Omega.$$

The quantity $\nu(\Omega)$ is well defined and $\nu(\Omega) \in (0, \infty]$. We have that $\nu(\Omega) < \infty$ if and only if $\varphi'_t(a) < 1$ for some t (if and only if $\varphi'_t(a) < 1$ for all t). In this case, we have that

$$\varphi'_t(a) = \exp\left(-\frac{\pi t}{\nu(\Omega)}\right),$$

for all $t \geq 0$ [2, Theorem 2.1]. Let us denote $V(\Omega) = \cap_{t \geq 0}(\Omega + t)$. The set $V(\Omega)$ is called the invariant set associated with Ω . The invariant set can be empty. If it is not empty, then it can be represented as at most a countable family of disjoint connected components V_k . Each component V_k is either an open strip or a halfplane parallel to the real axis. We denote by $\beta_k(\Omega)$ the width of the invariant strip V_k . By [2, Theorems 2.5 and 2.6], there is a bijection from the set of all the invariant strips of the invariant set and the set of repulsive regular boundary fixed points of the functions of the semigroup. In fact, if ξ_k is a repulsive regular boundary fixed point of Φ with associated strip V_k , then

$$\varphi'_t(\xi_k) = \exp\left(\frac{\pi t}{\beta_k(\Omega)}\right),$$

for all $t \geq 0$.

Now, take positive numbers $\alpha_1, \dots, \alpha_n$ with $\sum_{k=1}^n \alpha_k = 1$. Consider the domain

$$\Omega = \{z \in \mathbb{C} : |\operatorname{Im}(z)| < \frac{1}{2}\} \setminus \bigcup_{k=1}^{n-1} \{z \in \mathbb{C} : \operatorname{Im}(z) = -\frac{1}{2} + \sum_{j=1}^k \alpha_j \text{ and } \operatorname{Re}(z) < \gamma_k\},$$

where γ_k is a negative real number. Take h a Riemann map of Ω such that $h(0) = 0$ and the semigroup given by $\varphi_t(z) = h^{-1}(h(z) + 1)$ for all $t \geq 0$ and $z \in \mathbb{D}$. Then the Denjoy-Wolff point of the functions of the semigroup is a point $a \in \partial\mathbb{D}$, it has n different repulsive regular boundary fixed points $\xi_1, \dots, \xi_n$, and

$$\varphi'_t(a) = \exp(-\pi t) \quad \text{and} \quad \varphi'_t(\xi_k) = \exp\left(\frac{\pi t}{\alpha_k}\right) \quad \text{for all } t > 0.$$

Then,

$$\prod_{k=1}^n \varphi'_t(\xi_k)^{\alpha_k^2} = \exp \left(\sum_{k=1}^n \alpha_k^2 \frac{\pi t}{\alpha_k} \right) = \exp(\pi t) = \frac{1}{\varphi'_t(a)}.$$

This proves that the inequality in Theorem 1.2 is sharp.

4. ATTAINING THE EQUALITY BY MEANS OF QUADRATIC DIFFERENTIALS

Coming back again to the proof of Theorem 1.2, we see that any $\varphi \in \text{Hol}(\mathbb{D}, \mathbb{D})$ attaining the inequality given in the theorem necessarily satisfies that

$$\sum_{k=1}^n \alpha_k^2 m(\varphi(\widehat{D}_k), a, \xi_k) = \sum_{k=1}^n \alpha_k^2 m(\widehat{D}_k, a, \xi_k),$$

where $(\widehat{D}_1, \dots, \widehat{D}_n)$ is the extremal system of non-overlapping digons associated with the curve system $(\gamma_1, \dots, \gamma_n)$ and the vector α . According to [9, Section 2.7], and in these circumstances, each $\widehat{D}_k$ is then a strip domain in the trajectory structure of a unique quadratic differential $Q(z)dz^2$ and there is a conformal map $g_k(z)$, $z \in \widehat{D}_k$ that satisfies the differential equation

$$\alpha_k^2 \left(\frac{g'_k(z)}{g_k(z)} \right)^2 = 4\pi^2 Q(z)$$

and maps $\widehat{D}_k$ onto the strip $\mathbb{C} \setminus [0, \infty)$. Moreover,

$$Q(z)dz^2 = A \frac{\prod_{j=1}^{n-1} (z - e^{i\beta_k})^2}{(z - a)^2 \prod_{k=1}^n (z - \xi_k)^2} dz^2.$$

The complex constant A is defined by the following conditions: the unit circle is a trajectory of the differential, the integration of a branch of $\sqrt{Q(z)}dz$ along the orthogonal trajectory about 0 gives 1, and the integration of a branch of $\sqrt{Q(z)}dz$ along the orthogonal trajectory about 0 within each $\widehat{D}_k$ gives the height α_k . Each point $e^{i\beta_k}$ lies in the arc of the unit circle joining the points ξ_k and ξ_{k+1} . Since this extremal configuration is unique, so is the corresponding extremal function when fixing the points $e^{i\beta_k}$. Indeed, this function $w = \widehat{\varphi}(z)$ satisfies the complex differential equation

$$\frac{dw}{dz} = \frac{(w - a) \prod_{j=1}^{n-1} (z - e^{i\beta_k}) \prod_{k=1}^n (w - \xi_k)}{(z - a) \prod_{j=1}^{n-1} (w - e^{i\beta_k}) \prod_{k=1}^n (z - \xi_k)},$$

and the domain $\widehat{\varphi}(\mathbb{D})$ is the unit disk $\mathbb{D}$ minus at most $n - 1$ analytic arcs starting at the points $e^{i\beta_k}$ along the trajectories of the quadratic differential $Q(w)dw^2$. Their length depends on concrete values of the components of the vector α and on the angular derivative $\varphi'(a)$. In particular, all of the extremal functions are of the same type as those described in section three.

The connection between the two approaches given in this section and section three is clear. Namely, given the vector α , the orbits of points under the extremal dynamics considered in section 3 coincide with the trajectories of the quadratic differentials in this section.
